ABSTRACT

Simultaneous CO$_2$ concentration and temperature have been performed inside a fired engine. A model has been developed to accurately compute the theoretical CO$_2$ CARS spectra at high pressure and high temperature needed to process the experimental data. To overcome the main difficulties encountered when achieving measurements into an engine (i.e. cycle-to-cycle variations and beam steering by density gradients), the shot-by-shot referencing technique and the in-situ referencing technique using N$_2$ to determine [CO$_2$] were used.

In the burnt gas the CO$_2$ CARS signal is weak and only a rough estimation of the concentration has been achieved so far.

During the compression stroke the signal is much stronger (due to the lower temperature) despite the weak amount of CO$_2$ and accurate measurements could be performed. The correlations found between temperature and CO$_2$ concentration and the variation of [CO$_2$] with the crank angle, suggest that the mixture of fresh and residual gases is inhomogeneous.

INTRODUCTION

Optimizing the balance between fuel economy, emissions and performance is the challenge met when designing modern IC engine. Without doubt the success will result thanks to a better understanding of the process which control the combustion. As a part of the research effort aimed at this goal, new optical diagnostic techniques have been adapted to engine as soon they became available. CARS, in particular was very early applied to engine, mainly for thermometry purpose [1,4].

Measurements by CARS into an engine is complicated, compared to measurements performed into less hostile devices, by the following specific features:

- The size of the chamber is small and has to be accessed through windows.
- Strong temperature and density gradients are likely.
- The ranges of temperature, pressure and species concentration encountered are large.
- Cycle-to-cycle variations add difficulties to the unsteady and turbulent characters of the combustion process.

To overcome the problems one has to develop his own strategy which would mainly depend upon the answer given to the last point.

Unlike most of the authors we have chosen to perform single-shot measurements. In the next paragraph, devoted to the experimental approach, we will analyse the implications of such a choice.

The last paragraph is devoted to presentation and discussion of the results we have obtained in measuring simultaneously the temperature and the concentration of CO$_2$ into an engine.

EXPERIMENTAL

Engine

The measurements have been performed in an engine developed by G.S.M. ("Groupeement Scientifique Moteur") which has the needed optical access. An elongated piston, bolted over the piston of a production engine crank case, slides into a chrome cylinder liner without lubricating oil. The combustion chamber has a cylindrical shape (flat cylinder heat and flat piston) except in a crosspiece holding rectangular windows (20mm wide and 11.8mm high). The compression ratio is 4.7 : 1 and the engine is fueled with isoctane thanks to a commercial carburettor. In the experiment reported here the engine was ignited with three spark plugs fired simultaneously at 21 degrees before TDC. The plugs are regularly spaced around the circumference of the crosspiece which holds the windows.

The CARS measurements are performed at a given crank angle about every 1 second. The pressure is measured by a transducer as function pressure traces of the crank angle, at each cycle, but only cycles during which a CARS measurements occurs are stored.

CARS systems

The CARS system was developed in collaboration with ONERA and SOPRA. It consists
of a frequency-doubled single-mode Nd:YAG laser which generates the pump beam and of two independent dye lasers, pumped synchronously by parts of the YAG laser output. One of them is a broadband laser (60 cm\(^{-1}\)) allowing determination of the temperature on N\(_2\), the other one is a narrowband laser (0.25 cm\(^{-1}\)) tuned on a Raman-active transition of the second species to be studied, CO\(_2\) in the present work.

The beams are first focused by a 0.3m focal length achromat into a cell filled with 3bars or Argon. The two non-resonant anti-Stokes signals (reference signals) generated in the cell are isolated from the laser beams with dichroic filters and send to the upper part of the slit of a spectrograph. The laser beams are then focused again by a 0.2m focal length achromat into the center of the combustion chamber, and the two anti-Stokes signal (one from N\(_2\), the other from CO\(_2\)) are send to the lower part of the slit of the spectrograph. At the exit of the spectrograph four signals (two references and two signals) are received on four distinct locations on an ISIT Vidicon camera. Two mirrors inside the spectrograph allow the CO\(_2\) and N\(_2\) spectra to be collected on the same receptor with the spectral dispersion needed to obtain the good spectral resolution (1.2 cm\(^{-1}\)) required for accurate determination of the temperature, despite the spectral gap between the two spectra. Figure 1 shows an example of the four signals registered on the camera.

\[\text{Fig.1 - Reference and Measurement signals on the camera}\]

The choice of a short focal length (0.2m) lens to focus the lasers beam inside the combustion chamber is imposed by the presence of the windows because it is necessary to keep the size of the beams large enough when they cross the windows to avoid optical damages. As a consequence the size of the volume of interaction if the BOXCARS configuration was used would be very small. The CARS signals would be very weak and the signal-to-noise ratio too poor to allow good single-shots measurements. To perform single-shot measurements it is therefore necessary to have recourse to the colinear beam configuration in detriment to the spatial resolution. The probe volume is cylindrical, 1cm in length and 100\(\mu\)m in diameter. With this configuration it was possible to eliminate the non-resonant background, using the crossed polarization technique (which decreases the signal by a factor of 16). This procedure which is very useful for obtaining a good determination of the temperature (otherwise accurate knowledge of the non-resonant background is necessary [5]) was absolutely needed for the concentration measurements.

\[\text{Processing}\]

Four signals are collected on the ISIT camera.

Two reference signals

\[\begin{align*}
P^\text{ref}_{\text{CO}_2} &= C_1 P^2 P_{\text{CO}_2} |X^\text{AR}|^2 N^2_{\text{ref}} \quad (1) \\
P^\text{ref}_{N_2} &= C_3 P^2 P_{N_2} |X^\text{AR}|^2 N^2_{\text{ref}} \quad (2)
\end{align*}\]

and two measurement signals

\[\begin{align*}
P^\text{mes}_{\text{CO}_2} &= A C_2 P^2 P_{\text{CO}_2} |X_{\text{CO}_2}|^2 N^2_{\text{CO}_2} \quad (3) \\
P^\text{mes}_{N_2} &= A C_4 P^2 P_{N_2} |X_{N_2}|^2 N^2_{N_2} \quad (4)
\end{align*}\]

\(P_{\text{CO}_2}, P_{N_2}\) are respectively the pump power and the Stokes powers.

\(X^\text{AR}\) is the non-resonant susceptibility of Argon.

\(N^2_{\text{CO}_2}, N^2_{N_2}, N^2_{\text{ref}}\) are the molecular density of CO\(_2\), N\(_2\), and Argon respectively.

\(C_1, C_2, C_3, C_4\) are constants.

\(A\) is a factor taking into account the attenuation of the measured signals due to various effects in the engine : beam steering effects, optical transmission. The basis of the method is to assume that \(A\) is the same for the nitrogen signal and for the CO\(_2\) signal.

The N\(_2\) spectra are first processed to determine the temperature. Ratio

\[\frac{P^\text{mes}_{N_2}}{P^\text{ref}_{N_2}}\]

is computed as function of \(N^2_{N_2}\) in dividing channel by channel the measurement signal by the reference signal. It represents the rovibrational spectra of N\(_2\), in relative value, free of inhomogeneity of the dye laser.

It can be compared, according to a well established routine to theoretical spectral of N\(_2\) (at the pressure measured simultaneously in the engine), and the temperature is obtained.

The theoretical N\(_2\) spectra and the fitting procedure are those developed by ONERA\([6]\).

Figure 2 gives an example of temperature determination. The experimental curve has been taken in the engine at 660 crank angle degrees.
Fig. 2 - Determination of the temperature
Experimental (dots) and theoretical
(solid line) N₂ spectra.

Once the temperature known the CO₂
concentration can be determined. Summations
(normalized by the reference signals) over the
bandwidths of the dye lasers are then computed:

\[ R_{N_2} = \sum \text{modes } \omega_{AS} \quad \text{and} \quad R_{CO_2} = \sum \text{modes } \omega_{AS} \]

They do not depend on the laser intensities
but they still depends on beam steering effects.
The in situ referencing concept is used in computing \( R \): \n
\[
R = \frac{R_{CO_2}}{T_{N_2}} \cdot \frac{N_{CO_2}}{N_{N_2}} \cdot \frac{\int \omega_{CO_2} f(\omega) d\omega}{\int \omega_{N_2} g(\omega) d\omega} K \quad (6)
\]

Constant \( K \) is determined by calibration in
a known mixture of \( N_2 \) and \( CO_2 \) at ambient
temperature. The integrals are computed using
theoretical spectra taking into account the
apparatus functions \( f(\omega) \) and \( g(\omega) \) of the lasers.

The accuracy of the determination depends
obviously on the quality of the theoretical
\( N_2 \) and \( CO_2 \) spectra. The model for \( CO_2 \) has been
developed in our laboratory in collaboration with ONERA and the University of Besançon.
Essentially it is based on the energy gap model.
It is described in detail in [7].

Figure 3 gives examples of the good
agreement found between the model and
experimental spectra recorded in a cell
containing 50% of \( CO_2 \) in nitrogen.

RESULTS AND DISCUSSION

Preliminary measurements have been made in
a cell, at room temperature, to test the
accuracy of the method. A mixture of 88.5% \( N_2 \),
4.5% CO and 7% \( CO_2 \) under a pressure of 4 Bar was
used. The standard deviation of 100 measurements
of ratio \( R \) was found to be 10%. As the
concentration of \( CO_2 \) appears squared in relation
(5) a standard deviation of only 70% affects
this value.

These measurements could also be used to
determine constant \( K \). It appeared however that \( K \)
depends notably on the particular optical
alignment and laser adjusting and could vary from
one day to the other.

Therefore constant \( K \) was determined in
performing the measurements in filling the
engine chamber with a flow of the \( CO_2 \), \( CO \), \( N_2 \)
mixture just before runing the engine.

Temperature and \( CO_2 \) concentration have been
measured at various crank angles. In the burnt
gas at 660 crank angle degrees the pressure is 1
Bar and the temperature was found to be 1200K
(\( \sigma = 50K \)). Due to high temperature and low
pressure, the \( CO_2 \) signal was weak and only a
rough approximation of the \( CO_2 \) concentration
could be deduced. The value was found close to
the 12.5% value measured in the exhaust gases by
classical analysis. No attempt was made so far
to perform measurements in the burnt gas earlier
in the cycle.
During the compression stroke the temperature is lower and good signal-to-noise ratios are obtained despite the weaker amount of CO₂ (present in the residual). Table 1 gives the mean temperature, pressure and CO₂ concentration as well as their respective σ. Measurements have been averaged over about 100 shots.

Table 1

Figure 4 shows the mean value of [CO₂] as function of the crank angle. Within the uncertainties (± σ), [CO₂] is constant and would correspondant to a residual fraction of 15%. However a variation of the concentration with the crank angle can be seen, which would correspond to inhomogeneity of the gases. The measurements are performed at the top of the combustion chamber and, at the beginning of the compression stroke, it is possible that a larger amount of exhaust gas exists in the bottom of the cylinder than in the top, near the valves.

![Figure 4 - CO₂ concentration vs crank angle](image)

The likely inhomogeneity of the charge can also be shown in analyzing Fig.5 where the single-shot determinations of [CO₂] are plotted versus the corresponding measured temperatures. A clear correlation between [CO₂] and T can be seen: the larger the temperature, the larger the concentration of CO₂ (measurements performed at the other crank angles give the same results). It can be thought that measurements are performed in pockets containing more or less exhaust gases.

![Figure 5 - Correlation between [CO₂] and temperature at 180 crank angle degrees](image)

The size of the probe volume (1cm in length) is probably larger than the size of pockets and the value found are averaged over the content of the probe volume. Of course, one would like to have a better spatial resolution. It should be clearly understood that such correlations can be done thanks to single-shot determination of T and [CO₂] and that, so far, can be performed only with a poor spatial resolution.
